**Abstract.** We study optimization versions of Graph Isomorphism. Given two graphs  $G_1, G_2$ , we are interested in finding a bijection  $\pi$  from  $V(G_1)$  to  $V(G_2)$  that maximizes the number of matches (edges mapped to edges or non-edges mapped to non-edges). We give an  $n^{O(\log n)}$  time approximation scheme that for any constant factor  $\alpha < 1$ , computes an  $\alpha$ -approximation. We prove this by combining the  $n^{O(\log n)}$  time additive error approximation algorithm of Arora et al. [*Math. Program.*, 92, 2002] with a simple averaging algorithm. We also consider the corresponding minimization problem (of mismatches) and we prove that it is NP-hard to  $\alpha$ -approximate for any constant factor  $\alpha$ . Further, we show that it is also NP-hard to approximate the maximum number of edges mapped to edges beyond a factor of 0.94.

We also explore these optimization problems for bounded color class graphs which is a well studied tractable special case of Graph Isomorphism. Surprisingly, the bounded color class case turns out to be harder than the uncolored case in the approximate setting.

## 1 Introduction

The graph isomorphism problem (GI for short) is a well-studied computational problem: Formally, given two graphs  $G_1$  and  $G_2$  on  $n$  vertices, decide if there exists a bijection  $\pi: V(G_1) \rightarrow V(G_2)$  such that  $(u, v) \in E_1$  iff  $(\pi(u), \pi(v)) \in E_2$ . It remains one of the few problems that are unlikely to be NP-complete and for which no polynomial time algorithm is known.

Though the fastest known graph isomorphism algorithm for general graphs has running time  $2^{O(\sqrt{n \log n})}$  [5], polynomial-time algorithms are known for many interesting subclasses, e.g. bounded degree graphs [18], bounded genus graphs [20], and bounded eigenvalue multiplicity graphs [4].

**Motivation and Related Work.** In this paper we study a natural optimization problem corresponding to the graph isomorphism problem where the objective is to compute a bijection that *maximizes* the number of edges getting

---

<sup>\*</sup> An abbreviated version of this paper will be published in the proceedings of MFCS 2012.

mapped to edges and non-edges getting mapped to non-edges. The main motivation for this study is to explore if approximate isomorphisms can be computed efficiently, given that the best known algorithm for computing exact isomorphisms has running time  $2^{O(\sqrt{n \log n})}$ . The starting point of our investigation is a well-known article of Arora, Frieze and Kaplan [2] in which they study approximation algorithms for a quadratic assignment problem based on randomized rounding. Among the various problems they study, they also observe that approximate graph isomorphisms between  $n$  vertex graphs can be computed up to *additive error*  $\varepsilon n^2$  in time  $n^{O(\log n / \varepsilon^2)}$ . We show that this algorithm can be modified to obtain a multiplicative error approximation scheme for the problem. However, when we consider other variants of approximate graph isomorphism, they turn out to be much harder algorithmically.

To the best of our knowledge, the only previous theoretical study of approximate graph isomorphism is this work of Arora, Frieze and Kaplan [2]. However, the problem of approximate isomorphism and more general notions of graph similarity and graph matching has been studied for several years by the pattern matching community; see e.g. the survey article [7]. That line of research is not really theoretical. It is based on heuristics that are experimentally studied without rigorous proofs of approximation guarantees. Similarly, the general problem of graph edit distance [9] also encompasses approximate graph isomorphism. Both graph matchings and graph edit distance give rise to a variety of natural computational problems that are well studied.

**Optimization versions of graph isomorphism.** Let  $G_1 = (V_1, E_1)$  and  $G_2 = (V_2, E_2)$  be two input graphs on the same number  $n$  of vertices. We consider the following optimization problems:

- Max-EGI: Given  $G_1, G_2$ , find a bijection  $\pi: V_1 \rightarrow V_2$  that maximizes the number of matched edges, i.e.,  $me(\pi) = \|\{(u, v) \in E_1 \mid (\pi(u), \pi(v)) \in E_2\}\|$ .
- Max-PGI: Given  $G_1, G_2$ , find a bijection  $\pi: V_1 \rightarrow V_2$  that maximizes matched vertex pairs, i.e.,  $mp(\pi) = me(\pi) + \|\{(u, v) \notin E_1 \mid (\pi(u), \pi(v)) \notin E_2\}\|$ .
- Min-EGI: Given  $G_1, G_2$ , find a bijection  $\pi: V_1 \rightarrow V_2$  that minimizes mismatched edges, i.e.,  $\overline{me}(\pi) = \|\{(u, v) \in E_1 \mid (\pi(u), \pi(v)) \notin E_2\}\|$ .
- Min-PGI: Given  $G_1, G_2$ , find a bijection  $\pi: V_1 \rightarrow V_2$  that minimizes mismatched pairs, i.e.,  $\overline{mp}(\pi) = \overline{me}(\pi) + \|\{(u, v) \notin E_1 \mid (\pi(u), \pi(v)) \in E_2\}\|$ .

As mentioned above, Max-PGI was studied before in [2]. Max-EGI can also be viewed as an optimization variant of subgraph isomorphism.

Clearly,  $mp(\pi) + \overline{mp}(\pi) = \binom{n}{2}$  and  $me(\pi) + \overline{me}(\pi) = \|E_1\|$ . Thus solving one of the maximization problems with additive error is equivalent to solving the corresponding minimization problem with the same additive error. However, the minimization problems behave differently for multiplicative factor approximations, so we study them separately.

**Bounded color class graph isomorphism.** A natural restriction of GI is to vertex-colored graphs  $(G_1, G_2)$  where  $V(G_1) = C_1 \cup C_2 \cup \dots \cup C_m$  and

$V(G_2) = C'_1 \cup C'_2 \cup \dots \cup C'_m$ , and  $C_i, C'_i$  contain the vertices of  $G_1$  and  $G_2$ , respectively, that are colored  $i$ . The problem is to compute a color-preserving isomorphism  $\pi$  between  $G_1$  and  $G_2$ , i.e., an isomorphism  $\pi$  such that for any vertex  $u$ ,  $u$  and  $\pi(u)$  have the same color. The bounded color-class version  $\text{Gl}_k$  of  $\text{Gl}$  consists of instances such that  $\|C_i\| = \|C'_i\| \leq k$  for all  $i$ . For  $\text{Gl}_k$ , randomized [3] and deterministic [8] polynomial time algorithms are known.

It is, therefore, natural to study the optimization problems defined above in the setting of vertex-colored graphs where the objective function is optimized over all color-preserving bijections  $\pi: V_1 \rightarrow V_2$ . We denote these problems as  $\text{Max-PGl}_k$ ,  $\text{Max-EGl}_k$ ,  $\text{Min-PGl}_k$  and  $\text{Min-EGl}_k$ , where  $k$  is a bound on the number of vertices having the same color.

**Overview of the results.** We first recall the notion of an  $\alpha$ -approximation algorithm for an optimization problem. We call an algorithm  $\mathcal{A}$  for a maximization problem an  $\alpha$ -approximation algorithm, where  $\alpha < 1$ , if given an instance  $\mathcal{I}$  of the problem with an optimum  $\text{OPT}(\mathcal{I})$ ,  $\mathcal{A}$  outputs a solution with value  $\mathcal{A}(\mathcal{I})$  such that  $\mathcal{A}(\mathcal{I}) \geq \alpha \text{OPT}(\mathcal{I})$ . Similarly, for a minimization problem, we say  $\mathcal{B}$  is a  $\beta$ -approximation algorithm for  $\beta > 1$ , if for any instance  $\mathcal{I}$  of the problem with an optimum  $\text{OPT}(\mathcal{I})$ ,  $\mathcal{B}$  outputs a solution with value  $\mathcal{B}(\mathcal{I})$  such that  $\mathcal{B}(\mathcal{I}) \leq \beta \text{OPT}(\mathcal{I})$ .

**Theorem 1.** *For any constant  $\alpha < 1$ , there is an  $\alpha$ -approximation algorithm for  $\text{Max-PGl}$  running in time  $n^{O(\log n / (1-\alpha)^4)}$ .*

We obtain the  $\alpha$ -approximation algorithm for  $\text{Max-PGl}$  by combining the  $n^{O(\log n)}$  time additive error algorithm of [2] with a simple averaging algorithm.

Next we consider the  $\text{Max-EGl}$  problem. Langberg et al. [16] proved that there is no polynomial-time  $(1/2 + \varepsilon)$ -approximation algorithm for the Maximum Graph Homomorphism problem for any constant  $\varepsilon > 0$  assuming that a certain refutation problem has average-case hardness (for the definition and details of this assumption we refer the reader to [16]). We give a factor-preserving reduction from the Maximum Graph Homomorphism problem to  $\text{Max-EGl}$  thus obtaining the following result.

**Theorem 2.** *There is no  $(\frac{1}{2} + \varepsilon)$ -approximation algorithm for  $\text{Max-EGl}$  for any constant  $\varepsilon > 0$  under the same average-case hardness assumption of [16].*

We observe that unlike in the case of  $\text{Gl}_k$ , where polynomial time algorithms are known [3,8,19], in the optimization setting, these problems are computationally harder. We prove the following theorem by giving a factor-preserving reduction from  $\text{Max-2Lin-2}$  (e.g. see [15]) to  $\text{Max-PGl}_k$  and  $\text{Max-EGl}_k$ .

**Theorem 3.** *For any  $k \geq 2$ ,  $\text{Max-PGl}_k$  and  $\text{Max-EGl}_k$  are NP-hard to approximate beyond a factor of 0.94.*

Since, assuming the Unique Games Conjecture (UGC for short) of Khot [14], it is NP-hard to approximate  $\text{Max-2Lin-2}$  beyond a factor of 0.878 [15], the same

bound holds under UGC for  $\text{Max-PGI}_k$  and  $\text{Max-EGI}_k$  by the same reduction. Since  $\text{Max-PGI}_k$  and  $\text{Max-EGI}_k$  are easily seen to be instances of generalized 2CSP, they have constant factor approximation algorithms, for a constant factor depending on  $k$ . In fact, it turns out that  $\text{Max-EGI}_2$  and  $\text{Max-PGI}_2$  are tightly classified by  $\text{Max-2Lin-2}$  with almost matching upper and lower bounds (details are given in Section 2). However, we do not know of similar gap-preserving reductions from general unique games (with alphabet size more than 2) to  $\text{Max-PGI}_k$  or  $\text{Max-EGI}_k$  for any  $k$ .

The following results show that the complexity of Min-PGI and Min-EGI is significantly different from Max-PGI and Max-EGI.

**Theorem 4.** *There is no polynomial time approximation algorithm for Min-PGI with any multiplicative approximation guarantee unless  $\text{GI} \in \text{P}$ .*

**Theorem 5.** *Min-PGI does not have a PTAS unless  $\text{P} = \text{NP}$ .*

**Theorem 6.** *There is no polynomial time approximation algorithm for Min-EGI with any multiplicative approximation guarantee unless  $\text{P} = \text{NP}$ .*

Finally, we turn our attention to the minimization problems  $\text{Min-PGI}_k$  and  $\text{Min-EGI}_k$  on bounded color-class graphs. We prove that  $\text{Min-PGI}_k$  is as hard as the minimization version of  $\text{Max-2Lin-2}$ , known in literature as the  $\text{Min-Uncut}$  problem, and that  $\text{Min-EGI}_4$  is inapproximable for any constant factor unless  $\text{P} = \text{NP}$  by reducing the Nearest Codeword Problem (NCP) to it.

**Outline of the paper.** In Section 2, we study the maximization problems  $\text{Max-PGI}$  and  $\text{Max-EGI}$ , and in Section 3 the corresponding minimization problems  $\text{Min-PGI}$  and  $\text{Min-EGI}$ . Section 4 concludes with some open problems.

## 2 Maximizing the number of matches

We first observe that computing optimal solutions to  $\text{Max-PGI}$  is NP-hard via a reduction from  $\text{CLIQUE}$ .

**Lemma 7.** *Computing optimal solutions to  $\text{Max-PGI}$  instances is NP-hard.*

*Proof.* Let  $(G, k)$  be an instance of the  $\text{CLIQUE}$  problem. Define the graphs  $G_1 = G$  and  $G_2 = K_k \cup \bar{K}_{n-k}$ , i.e., a  $k$ -clique and  $n - k$  isolated vertices. Let  $\pi_{opt}$  be a bijection that achieves the optimum value for this  $\text{Max-PGI}$  instance. Then  $G$  has a  $k$ -clique if and only if  $mp(\pi_{opt}) = \binom{n}{2} - \|E_G\| + \binom{k}{2}$ .  $\square$

Next we give a general method for combining an additive error approximation algorithm for  $\text{Max-PGI}$  with a simple averaging approximation algorithm to design an  $\alpha$ -approximation algorithm for  $\text{Max-PGI}$  for any constant  $\alpha < 1$ .

**Lemma 8.** *Suppose  $\mathcal{A}$  is an algorithm such that for any  $\varepsilon > 0$ , given a Max-PGI instance in form of two  $n$ -vertex graphs  $G_1 = (V_1, E_1)$  and  $G_2 = (V_2, E_2)$ , computes a bijection  $\pi: V_1 \rightarrow V_2$  such that  $mp(\pi) \geq \text{OPT} - \varepsilon n^2$  in time  $T(n, \varepsilon)$ . Then there is an algorithm that computes for each  $\alpha < 1$  an  $\alpha$ -approximate solution for any Max-PGI instance  $(G_1, G_2)$  in time  $O(T(n, (1 - \alpha)^2/9) + n^3)$ .*

*Proof.* Without loss of generality we can assume  $V_1 = V_2 = [n]$ . We denote the number of edges in  $G_i$  by  $t_i$  and the number of non-edges by  $\bar{t}_i$ . Notice that the optimum for Max-PGI satisfies  $\text{OPT} \leq t_1 + \bar{t}_2$ . Let  $\pi: [n] \rightarrow [n]$  be a permutation chosen uniformly at random. Then, an easy calculation shows that the expected number  $s$  of matched pairs is

$$s = \frac{t_1 t_2 + \bar{t}_1 \bar{t}_2}{\binom{n}{2}} = \frac{\binom{n}{2} - \bar{t}_2}{\binom{n}{2}} t_1 + \frac{\bar{t}_2}{\binom{n}{2}} \left( \binom{n}{2} - t_1 \right) = t_1 + \bar{t}_2 - \frac{2t_1 \bar{t}_2}{\binom{n}{2}}.$$

It is not hard to see that one can deterministically compute a permutation  $\sigma$  such that  $mp(\sigma) \geq s$ ; we defer this detail to the end of the proof. We now show how this can be combined with the additive error approximation algorithm  $\mathcal{A}$  for Max-PGI to obtain an  $\alpha$ -approximation algorithm for Max-PGI. This combined algorithm distinguishes two cases based on the number of edges and non-edges in  $G_1$  and  $G_2$ , respectively.

**Case 1** ( $\min\{t_1, \bar{t}_2\} \leq (1 - \alpha)\binom{n}{2}/2$ ): In this case we compute a permutation  $\sigma$  with  $mp(\sigma) \geq s$ . Since

$$t_1 \bar{t}_2 = \max\{t_1, \bar{t}_2\} \min\{t_1, \bar{t}_2\} \leq (t_1 + \bar{t}_2) (1 - \alpha) \binom{n}{2} / 2,$$

it follows that

$$t_1 + \bar{t}_2 - 2t_1 \bar{t}_2 / \binom{n}{2} \geq \alpha (t_1 + \bar{t}_2) \geq \alpha \text{OPT}.$$

**Case 2** ( $\min\{t_1, \bar{t}_2\} > (1 - \alpha)\binom{n}{2}/2$ ): In this case we use algorithm  $\mathcal{A}$  with  $\varepsilon = (1 - \alpha)^2/9$  to obtain a permutation  $\pi$  with  $mp(\pi) \geq \text{OPT} - \varepsilon n^2$ . Since  $t_1 + \bar{t}_2 + \bar{t}_1 + t_2 = 2\binom{n}{2}$ , either  $t_1 + \bar{t}_2 \leq \binom{n}{2}$  or  $\bar{t}_1 + t_2 < \binom{n}{2}$ . Without loss of generality assume  $t_1 + \bar{t}_2 \leq \binom{n}{2}$  (otherwise we interchange  $G_1$  and  $G_2$ ), implying that either  $t_1 \leq \binom{n}{2}/2$  or  $\bar{t}_2 \leq \binom{n}{2}/2$ . Further, since the expected value of  $mp(\pi)$  when  $\pi$  is picked at random is  $t_1 + \bar{t}_2 - 2t_1 \bar{t}_2 / \binom{n}{2}$ , it follows that for sufficiently large  $n$ ,

$$\text{OPT} \geq t_1 - t_1 \bar{t}_2 / \binom{n}{2} + \bar{t}_2 - t_1 \bar{t}_2 / \binom{n}{2} \geq \frac{\min\{t_1, \bar{t}_2\}}{2} > \frac{1 - \alpha}{4} \binom{n}{2} \geq \frac{\varepsilon n^2}{1 - \alpha}.$$

Hence,  $mp(\pi) \geq \text{OPT} - \varepsilon n^2 \geq \alpha \text{OPT}$ .

It remains to show how a permutation which achieves at least the expected number  $s$  of matched pairs can be computed deterministically. Suppose that  $\sigma: [i] \rightarrow [n]$  is a *partial permutation*. Let  $\pi: [n] \rightarrow [n]$  be a random permutation

that extends  $\sigma$ , i.e.,  $\pi(j) = \sigma(j)$  for  $j \in [i]$ . Let  $s(\sigma)$  denote the expected number of matched pairs over random permutations  $\pi$  that extend  $\sigma$ . It is easy to see that we can compute  $s(\sigma)$  in polynomial time. We do this by counting the pairs in three parts: (a) pairs with both end points in  $[i]$ , (b) pairs with both end points in  $[n] \setminus [i]$ , and (c) pairs with one end point in  $[i]$  and the other in  $[n] \setminus [i]$ . Matched pairs of type (a) depend only on  $\sigma$  and can be counted straightaway. The expected number of matched pairs of type (b) is computed exactly as  $s$  above (since  $\pi$  restricted on  $[n] \setminus [i]$  is random). The expected number of matched pairs of type (c) is given by  $\sum_{j \in [i]} \frac{n_j n_{\sigma(j)} + (n-i-n_j)(n-i-n_{\sigma(j)})}{n-i}$ , where  $n_j$  is the number of neighbors of  $j$  in the graph  $G_1$  contained in  $[n] \setminus [i]$  and  $n_{\sigma(j)}$  is the number of neighbors of  $\sigma(j)$  in the graph  $G_2$  contained in  $[n] \setminus \{\sigma(l) \mid l \in [i]\}$ . The entire computation of  $s(\sigma)$  takes  $O(n^2)$  time.

Now, for  $k \in [n] \setminus \{\sigma(l) \mid l \in [i]\}$ , let  $\sigma_k: [i+1] \rightarrow [n]$  denote the extension of  $\sigma$  by setting  $\sigma(i+1) = k$ . Since a random extension  $\pi$  of  $\sigma$  can map  $i+1$  uniformly to any  $k \in [n] \setminus \{\sigma(l) \mid l \in [i]\}$  it follows that

$$s(\sigma) = \frac{1}{n-i} \sum_k s(\sigma_k),$$

where the summation is over all  $k \in [n] \setminus \{\sigma(l) \mid l \in [i]\}$ .

Furthermore, each  $s(\sigma_k)$  is efficiently computable, as explained above. Reusing partial computations, we can find  $k$  such that  $s(\sigma_k) \geq s(\sigma)$  in time  $O(n^2)$ . Continuing thus, when we fix the permutation on all of  $[n]$  we obtain a  $\sigma$  with  $mp(\sigma) \geq s$  in  $O(n^3)$  time.  $\square$

Note that any polynomial time additive  $\varepsilon$ -error algorithm for Max-PGI, i.e., an algorithm running in time  $n^{\text{poly}(1/\varepsilon)}$  with an additive error  $\leq \varepsilon n^2$ , gives a polynomial time  $\alpha$ -approximation algorithm for Max-PGI running in time  $n^{\text{poly}(1/(1-\alpha))}$ .

To complete the proof of Theorem 1, we formulate Max-PGI as an instance of a quadratic optimization problem called the Quadratic Assignment Problem (QAP for short) as was done in [2] and use an additive error approximation algorithm for the Quadratic Assignment Problem due to Arora, Frieze and Kaplan [2].

Given  $\{c_{ijkl}\}_{1 \leq i,j,k,l \leq n}$ , the Quadratic Assignment Problem is to find an  $n \times n$  permutation matrix  $x = (x_{ij})$  that maximizes  $val(x) = \sum_{i,j,k,l} c_{ijkl} x_{ij} x_{kl}$ . An instance of Max-PGI consisting of graphs  $G_1 = ([n], E_1)$  and  $G_2 = ([n], E_2)$  can be naturally expressed as a QAP instance by setting

$$c_{ijkl} = \begin{cases} 1 & \text{if } (i, k) \in E_1 \text{ and } (j, l) \in E_2 \text{ or } (i, k) \notin E_1 \text{ and } (j, l) \notin E_2 \\ 0 & \text{otherwise.} \end{cases}$$

This ensures that  $val(x) = mp(\pi_x)$  for all permutation matrices  $x$  with corresponding permutation  $\pi_x$ ; in particular, the optimum solutions of the Max-PGI and QAP instances achieve the same value.

There is no polynomial time  $\alpha$ -approximation algorithm for QAP for any  $\alpha < 1$  unless  $P = NP$  [2]. Arora, Frieze and Kaplan in [2] give a general quasipolynomial time algorithm for QAP with an additive error. Formally, they prove the following theorem.

**Theorem 9 ([2]).** *There is an algorithm that, given an instance of QAP where each of the  $c_{ijkl}$  is bounded in absolute value by a constant  $c$  and given an  $\varepsilon$ , finds an assignment to  $x_{ij}$  such that  $\text{val}(x) \geq \text{val}(x^*) - \varepsilon n^2$  where  $x^*$  is the assignment which attains the optimum. The algorithm runs in time  $n^{O(c^2 \log n / \varepsilon^2)}$ .*

Thus for the Max-PGI problem, using Theorem 9 we can find a permutation  $\pi$  such that  $mp(\pi) \geq \text{OPT} - \varepsilon n^2$  in time  $n^{O(\log n / \varepsilon^2)}$ . Combining this with Lemma 8, we get an  $\alpha$ -approximation algorithm for Max-PGI running in time  $n^{O(\log n / (1-\alpha)^4)}$  and this completes the proof of Theorem 1.

In contrast to the quasi-polynomial time approximation scheme for Max-PGI, we now show that Max-EGI is likely to be  $(\frac{1}{2} + \varepsilon)$ -hard to approximate. To this end, define the Maximum Graph Homomorphism problem (MGH) first studied in [16]. Given two graphs  $G_1 = (V_1, E_1)$  and  $G_2 = (V_2, E_2)$ , MGH asks for a mapping  $\phi: V_1 \rightarrow V_2$  such that  $\|\{(u, v) \in E_1 \mid (\phi(u), \phi(v)) \in E_2\}\|$  is maximized. Langberg et al. [16] proved that MGH is hard to approximate beyond a factor of  $1/2 + \varepsilon$  under a certain average case assumption. To prove Theorem 2, we give a factor-preserving reduction from MGH to Max-EGI.

**Lemma 10.** *There is a polynomial time algorithm that for a given MGH instance  $\mathcal{I}$ , constructs a Max-EGI instance  $\mathcal{I}'$  with  $\text{OPT}(\mathcal{I}) = \text{OPT}(\mathcal{I}')$ .*

*Proof.* Given an MGH instance  $\mathcal{I} = (G_1, G_2)$ , we construct the Max-EGI instance  $\mathcal{I}' = (G'_1, G'_2)$  as follows. The graphs  $G'_1$  and  $G'_2$  both have vertex set  $V_1 \times V_2$ . For each edge  $(u_1, v_1)$  in the graph  $G_1$ , we put a single edge between the vertices  $(u_1, w_2)$  and  $(v_1, w_2)$  in  $E'_1$ , where  $w_2$  is an arbitrary but fixed vertex in  $V_2$ , and for each edge  $(u_2, v_2)$  in the graph  $G_2$ , we put all  $\|V_1\|^2$  edges between  $V_1 \times \{u_2\}$  and  $V_1 \times \{v_2\}$  in  $E'_2$ . It suffices to prove the following claim.

*Claim.* There is a mapping  $\phi: V_1 \rightarrow V_2$  such that  $\|\{(u, v) \in E_1 \mid (\phi(u), \phi(v)) \in E_2\}\| = k$  if and only if there is a permutation  $\pi: V_1 \times V_2 \rightarrow V_1 \times V_2$  such that  $\|\{(u, v) \in E'_1 \mid (\pi(u), \pi(v)) \in E'_2\}\| = k$ .

Given the mapping  $\phi$ , we construct the permutation  $\pi$  as follows: For each  $u_1 \in V_1$ ,  $\pi$  maps the vertex  $(u_1, w_2)$  of  $G'_1$  to the vertex  $(u_1, \phi(u_1))$  in  $G'_2$ . The remaining  $\|V_1\| \cdot \|V_2\| - \|V_1\|$  vertices of  $G'_1$  are mapped arbitrarily.

Then each edge  $(u_1, v_1) \in E_1$  is satisfied by  $\phi$  if and only if the corresponding edge between  $(u_1, w_2)$  and  $(v_1, w_2)$  in  $E'_1$  is satisfied by  $\pi$ . This follows from the fact that  $(\phi(u_1), \phi(v_1)) \in E_2$  if and only if there is an edge between  $(u_1, \phi(u_1))$  and  $(v_1, \phi(v_1))$  in  $E'_2$ .

Similarly, given a permutation  $\pi$  between  $G'_1$  and  $G'_2$ , we can obtain a mapping  $\phi: V_1 \rightarrow V_2$  achieving the same number of matched edges by letting  $\phi(u_1) = v_2$ , where  $v_2$  is the second component of the vertex  $\pi(u_1, w_2)$ .  $\square$

Unlike in the case of Max-PGI, we observe that there cannot be constant factor approximation algorithms for Max-PGI $_k$  for all constants. This is in interesting contrast to the fact that GI for graphs with bounded color-class size is in P. We now prove the hardness of approximating Max-PGI $_k$  and Max-EGI $_k$  for any  $k \geq 2$ .

We prove the hardness by exhibiting a factor-preserving reduction from Max-2Lin-2, which is hard to approximate above a guarantee of 0.94 unless  $P = NP$  [12]. The problem of Max-2Lin-2 can be stated thus

*Problem 11.* Given a set  $E \subseteq \{x_i + x_j = b \mid i, j \in [n], b \in \{0, 1\}\}$  of  $m$  equations over  $\mathbb{F}_2$ , find an assignment to the variables  $x_1, \dots, x_n$  that maximizes the number of equations satisfied.

The following lemma proves the factor-preserving reduction from Max-2Lin-2 to Max-PGI $_k$ . The proof for Max-EGI $_k$  is similar.

**Lemma 12.** *For any  $k \geq 2$ , there is a polynomial time algorithm that for a given Max-2Lin-2 instance  $\mathcal{I}$  constructs a Max-PGI $_{2k}$  instance  $\mathcal{I}'$  such that  $\text{OPT}(\mathcal{I}') = (2k)^2 \text{OPT}(\mathcal{I})$ .*

*Proof.* Let  $E \subseteq \{x_i + x_j = b \mid i, j \in [n], b \in \{0, 1\}\}$  be the equations of  $\mathcal{I}$ . As a first step, if there is a pair of equations  $x_i + x_j = 1$  and  $x_i + x_j = 0$  in  $E$ , remove both these equations and add a new equation  $y_i + y_j = 1$  on two new variables  $y_i$  and  $y_j$ . Let  $E'$  be the new set of equations obtained. Notice that  $\text{OPT}(E) = \text{OPT}(E')$ . We now describe the construction of the instance  $\mathcal{I}'$  of Max-PGI $_{2k}$ . For each variable  $x_i$ , put two sets of vertices  $V_i^0$  and  $V_i^1$  with  $k$  vertices each of color  $i$ . Let  $x_l + x_m = b$  be an equation in  $E'$ . In the graph  $G_1$ , add a complete bipartite graph between  $V_l^0$  and  $V_m^0$  and another complete bipartite graph between  $V_l^1$  and  $V_m^1$ . Similarly, add the complete bipartite graph between  $V_l^0$  and  $V_m^b$  and between  $V_l^1$  and  $V_m^{1 \oplus b}$  in  $G_2$ . If there is no equation in  $E'$  connecting the variables  $x_l$  and  $x_m$ , add a complete bipartite graph between the color classes  $l$  and  $m$  in  $G_1$  and the empty graph between  $l$  and  $m$  in  $G_2$ . Similarly, make all color classes cliques in  $G_1$  and independent sets in  $G_2$ . The idea is that assigning  $x_i \mapsto 0$  corresponds to mapping  $V_i^0$  and  $V_i^1$  to themselves, respectively, while assigning  $x_i \mapsto 1$  corresponds to mapping  $V_i^0$  to  $V_i^1$  and vice versa.

Given an assignment  $\sigma: [n] \rightarrow \{0, 1\}$  that satisfies  $t$  of the equations in  $E$ , let  $\pi_\sigma$  be the permutation that maps the  $j^{\text{th}}$  vertex in  $V_i^b$  to the  $j^{\text{th}}$  vertex in  $V_i^{b \oplus \sigma(i)}$ . For each satisfied equation  $x_i + x_j = b$ , this guarantees that all  $(2k)^2$  pairs in  $(V_i^0 \cup V_i^1) \times (V_j^0 \cup V_j^1)$  are matched. Thus  $\text{OPT}(\mathcal{I}') \geq mp(\pi_\sigma) = (2k)^2 t$ .

To prove the converse, let  $\pi: [n] \rightarrow [n]$  be a permutation with  $mp(\pi) = t$ . Define  $f_i$  as the number of vertices in  $V_i^0$  that are mapped to  $V_i^1$  by  $\pi$  (it is also the number of vertices in  $V_i^1$  mapped to  $V_i^0$ ). If  $f_i \in \{0, k\}$  for all  $i$ , it is straightforward to reverse the above construction, obtaining an assignment that satisfies  $mp(\pi)/(2k)^2$  equations.

If there is an  $i$  with  $f_i \notin \{0, k\}$ , let  $mp_{i,j}(\pi)$  denote the number of matched pairs between color classes  $i$  and  $j$ . Thus  $mp_{i,j}(\pi) = 4[(k - f_j)f_i + (k - f_i)f_j]$ . Define  $mp_i(\pi) = \sum_j mp_{i,j}(\pi)$ , obtaining

$$\begin{aligned} mp_i(\pi) &= \sum_j 4[(k - f_j)f_i + (k - f_i)f_j] \\ &= k^2 \sum_j 4 \left[ \left(1 - \frac{f_j}{k}\right) \frac{f_i}{k} + \left(1 - \frac{f_i}{k}\right) \frac{f_j}{k} \right]. \end{aligned}$$

Let  $mp'_i(\pi) = (1/k^2)mp_i(\pi) = \sum_j 4 [(1 - f'_j)f'_i + (1 - f'_i)f'_j]$  where  $f'_i = f_i/k$  and  $f'_j = f_j/k$ .

Define  $\pi_{i,b}$  (for  $b \in \{0, 1\}$ ) as the permutation that maps the  $j^{\text{th}}$  vertex of  $V_i^{b'}$  to the  $j^{\text{th}}$  vertex of  $V_i^{b \oplus b'}$ , and that acts like  $\pi$  on all other color classes. Thus,  $mp_i(\pi_{i,0}) = 4 \sum_j f'_j$  and  $mp_i(\pi_{i,1}) = 4 \sum_j (1 - f'_j)$ .

Since  $mp'_i(\pi)$  is a convex combination of  $mp_i(\pi_{i,0})$  and  $mp_i(\pi_{i,1})$ , one of the two must be at least as large as  $mp'_i(\pi)$ . Replace  $\pi$  by that permutation, and repeat this process until  $f_i \in \{0, k\}$  for all  $i$ .  $\square$

This construction still works if we replace  $mp(\pi)$  with  $me(\pi)$ , as for all equations  $x_i + x_j = b$  in  $E$ , exactly half of the possible edges between color classes  $i$  and  $j$  are present. It follows that there is a factor-preserving reduction from Max-2Lin-2 to Max-EGl $_{2k}$ .

**Lemma 13.** *For any  $k \geq 2$ , there is a polynomial time algorithm that for a given Max-2Lin-2 instance  $\mathcal{I}$  constructs a Max-EGl $_{2k}$  instance  $\mathcal{I}'$  such that  $\text{OPT}(\mathcal{I}') = 2k^2 \text{OPT}(\mathcal{I})$ .*

Since there is no  $\alpha$ -approximation algorithm for Max-2Lin-2 for  $\alpha > 0.94$  unless  $\text{P} = \text{NP}$  [12], Lemmas 12 and 13 complete the proof of Theorem 3 that there is no  $\alpha$ -approximation algorithm for Max-PGI $_k$  and Max-EGl $_k$  for  $\alpha > 0.94$  unless  $\text{P} = \text{NP}$ .

It is easy to see that for each constant  $k > 0$ , both Max-PGI $_k$  and Max-EGl $_k$  are subproblems of the generalized Max-2CSP( $q$ ), where  $q$  depends on  $k$ . Thus, both Max-PGI $_k$  and Max-EGl $_k$  have constant factor approximation algorithms by virtue of the semidefinite programming based approximation algorithm for Max-2CSP( $q$ ) [11]. The following lemma shows the reduction of Max-EGl $_2$  to Max-2CSP(2). The reduction from Max-PGI $_k$  and Max-EGl $_k$  to Max-2CSP( $q$ ) is similar.

**Lemma 14.** *There is a polynomial time algorithm that for two given vertex-colored graphs  $G_1$  and  $G_2$  where each color class has size at most 2, outputs a Max-2CSP(2) instance  $\mathcal{F} = \{f_1, \dots, f_m\}$  where  $m = \|E(G_1)\|$  and  $f_i: \{0, 1\}^2 \rightarrow \{0, 1\}$  such that there is a color-preserving bijection  $\pi: V(G_1) \rightarrow V(G_2)$  with  $me(\pi) = k$ , if and only if there is an assignment which satisfies  $k$  constraints in  $\mathcal{F}$ .*

*Proof.* For each color class  $C_i$ , we assign a variable  $x_i$ . For an edge  $e$  from  $C_i$  to  $C_j$  in  $G_1$ , construct the function  $f_e: \{0, 1\}^2 \rightarrow \{0, 1\}$  over the variables  $x_i$  and  $x_j$  as follows. Any boolean assignment to the variables can be looked upon as a permutation: If  $x_i \mapsto 0$ , then we have the identity permutation on  $C_i$ , otherwise the permutation swaps the vertices of  $C_i$ . The value  $f_e$  on that particular assignment is 1 if the permutation that it corresponds to sends the edge  $e$  to an edge in  $G_2$ . Hence there is an assignment that satisfies  $k$  constraints if and only if there is a permutation  $\pi$  with  $me(\pi) = k$ .  $\square$

As the problem of Max-2CSP(2) has an approximation algorithm with a guarantee of 0.874 [17], this implies an approximation algorithm for Max-EGl $_2$  with

the same guarantee and since **Max-2Lin-2** is hard to approximate beyond 0.878 under UGC [15], we have almost matching upper and lower bounds for **Max-EGI<sub>2</sub>** under UGC.

### 3 Minimizing the number of mismatches

We first consider the problems **Min-PGI** and **Min-EGI**, where the objective is to minimize the number of mismatched pairs and edges, respectively.

**Theorem 4.** *There is no polynomial time approximation algorithm for **Min-PGI** with any multiplicative approximation guarantee unless  $\text{GI} \in \text{P}$ .*

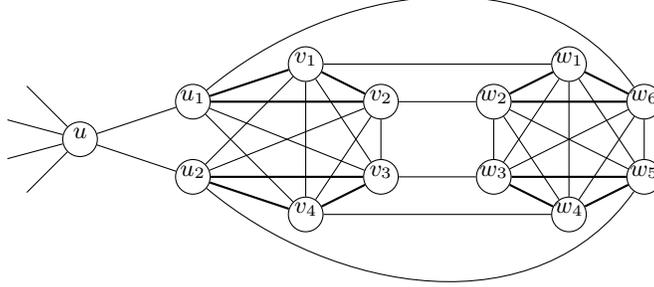

*Proof.* Assume that there is a polynomial time  $\alpha$ -approximation algorithm  $\mathcal{A}$  for **Min-PGI**. If the two input graphs  $G_1$  and  $G_2$  are isomorphic, then there is a bijection  $\pi: V_1 \rightarrow V_2$  such that  $\overline{m\overline{p}}(\pi) = 0$ , and if  $G_1$  and  $G_2$  are not isomorphic, then  $\overline{m\overline{p}}(\pi) > 0$  for all  $\pi$ . Thus, it immediately follows that  $G_1$  and  $G_2$  are isomorphic, if and only if  $\mathcal{A}$  outputs a bijection  $\sigma: V(G_1) \rightarrow V(G_2)$  with  $\overline{m\overline{p}}(\sigma) = 0$  (i.e., an isomorphism).  $\square$

In order to show that it is unlikely that **Min-PGI** has a polynomial time approximation scheme, we give a gap-preserving reduction from the Vertex-disjoint Triangle Packing problem (**VTP**) defined as follows: Given a graph  $G$  find the maximum number of vertex-disjoint triangles that can be packed into  $G$ . We look at the corresponding gap version of the **VTP** problem:

*Problem 15 (Gap-VTP $_{\alpha,\beta}$ ).* Given a graph  $G$  and  $\alpha > \beta$ ,

1. Answer YES, if at least  $\alpha n/3$  triangles can be packed into  $G$ .
2. Answer NO, if at most  $\beta n/3$  triangles can be packed into  $G$ .

It is known that the **VTP** problem does not have an algorithm which when given a graph and parameter  $\alpha$  as input, computes a vertex-disjoint triangle packing of size at least  $\alpha \text{OPT}$  in time  $O(n^{\text{poly}(1/(1-\alpha))})$  unless  $\text{P} = \text{NP}$  [6]. It is also known that for a fixed value of  $\beta < 1$ , **Gap-VTP $_{1,\beta}$**  is NP-hard on graphs of bounded degree [10,21]. Indeed, Petrank [21] gives a gap-preserving reduction from **3Sat** to **3DimensionalMatching**. It is not hard to see that replacing the hyperedges in the generated instances with triangles results in a gap-preserving reduction to **VTP**, as all triangles in the resulting graph correspond to a hyperedge. All vertices in the generated graph  $G$  have degree 4 or 6. Thus there is a  $\beta$  such that **Gap-VTP $_{1,\beta}$**  is NP-hard on such graphs. By attaching the gadget depicted in Fig. 1 to each vertex of degree 4 in  $G$ , we obtain a 6-regular graph  $G'$ , which we again consider as **VTP** instance. Let  $n$  and  $n'$  denote the number of vertices in  $G$  and  $G'$ , respectively. If  $G$  can be packed with  $n/3$  vertex-disjoint triangles, then  $G'$  can also be packed fully by vertex-disjoint triangles. If  $\text{OPT}(G) \leq \beta n/3$ , then  $\text{OPT}(G') \leq (1 - \frac{1-\beta}{13})n'/3$ . Thus there is a  $\beta'$  such that **Gap-VTP $_{1,\beta'}$**  is NP-hard on 6-uniform graphs.

**Fig. 1.** Converting a VTP instance  $G$  of degrees 4 and 6 to a 6-uniform VTP instance  $G'$

**Lemma 16.** *Given a  $\text{Gap-VTP}_{\alpha,\beta}$  instance  $\mathcal{I}$  (a 6-uniform graph on  $n$  vertices), in polynomial time we can find an Min-PGI instance  $\mathcal{I}'$  such that*

$$\begin{aligned} \text{OPT}(\mathcal{I}) \geq \frac{\alpha n}{3} &\Rightarrow \text{OPT}(\mathcal{I}') \leq 2n(2 - \alpha) \\ \text{OPT}(\mathcal{I}) \leq \frac{\beta n}{3} &\Rightarrow \text{OPT}(\mathcal{I}') \geq \frac{2n}{3}(4 - \beta) \end{aligned}$$

This reduction together with the hardness of VTP proves Theorem 5.

*Proof.* Let the instance  $\mathcal{I}$  of VTP be a 6-regular graph  $G$  on  $n$  vertices. We construct a Min-PGI instance  $\mathcal{I}' = (G_1, G_2)$  as follows:  $G_1 := G$  and  $G_2$  is a collection of  $n/3$  vertex-disjoint triangles on the same vertex set as  $G_1$ , without any further edges. Suppose  $\text{OPT}(\mathcal{I}) \geq \alpha n/3$ , then there is a permutation  $\pi$  that maps at least  $\alpha n/3$  triangles to vertex-disjoint triangles of  $G_1$ . Hence the number of edges of  $G_1$  that are mapped to non-edges of  $G_2$  is at most  $3n - \alpha n$ . Similarly, the number of edges of  $G_2$  that are images of non-edges of  $G_1$  is at most  $(1 - \alpha)n$ . Therefore,  $\text{OPT}(\mathcal{I}') \leq \overline{mp}(\pi) \leq 2n(2 - \alpha)$ .

Now suppose  $\text{OPT}(\mathcal{I}) \leq \beta n/3$ . Since  $G_1$  has at most  $\beta n/3$  disjoint triangles, any permutation  $\pi$  maps at least  $(1 - \beta)n/3$  non-edges of  $G_1$  to edges of  $G_2$ . Further, since  $G_1$  has at least  $2n$  edges more than  $G_2$  and since already at least  $(1 - \beta)n/3$  of the edges of  $G_2$  are images of non-edges of  $G_1$ ,  $\pi$  maps at least  $2n + (1 - \beta)n/3$  edges of  $G_1$  to non-edges of  $G_2$ . Thus we have

$$\overline{mp}(\pi) \geq \frac{n}{3}(1 - \beta) + 2n + \frac{n}{3}(1 - \beta) = \frac{2n}{3}(4 - \beta). \quad \square$$

Next we prove Theorem 6.

**Theorem 6.** *There is no polynomial time approximation algorithm for Min-EGI with any multiplicative approximation guarantee unless  $\text{P} = \text{NP}$ .*

*Proof.* The theorem follows from the following reduction from the CLIQUE problem. Given an instance  $(G, k)$  of CLIQUE, we construct the instance of Min-EGI

as follows.  $G_1$  consists of a  $k$ -clique and  $n - k$  independent vertices, and  $G_2 := G$ .  $(G, k) \in \text{CLIQUE}$  if and only if there exists a  $\pi$  such that in the Min-EGI problem  $\overline{m\bar{e}}(\pi) = 0$ . Hence any polynomial time approximation algorithm with a multiplicative guarantee for Min-EGI gives a polynomial time algorithm for CLIQUE.  $\square$

The input for the Min-Uncut problem is a set  $E \subseteq \{x_i + x_j = 1 \mid i, j \in [n]\}$  of  $m$  equations. The objective is to minimize the number of equations that must be removed from the set  $E$  so that there is an assignment to the variables that satisfy all the equations. This problem is known to be MaxSNP-hard [13], and assuming the Unique Games Conjecture, hard to approximate within any constant factor [14]. The following lemma shows that Min-PGI $_k$  is as hard as the Min-Uncut problem.

**Lemma 17.** *Let  $\mathcal{I}$  be an instance of Min-Uncut and let  $k$  be a positive integer. There is a polynomial time algorithm that constructs an instance  $\mathcal{I}'$  of Min-PGI $_{2k}$  such that  $\text{OPT}(\mathcal{I}') = (2k)^2 \text{OPT}(\mathcal{I})$ .*

The proof of this lemma is similar to the proof of Lemma 12. Given a set  $E \subseteq \{x_i + x_j = 1 \mid i, j \in [n]\}$  of equations over  $\mathbb{F}_2$ , we construct an instance  $\mathcal{I}'$  of Min-PGI $_{2k}$  exactly as described in the proof of Lemma 12. If the minimum number of equations that have to be deleted from  $E$  to make the rest satisfiable is at most  $t$ , then there is an assignment such that at most  $t$  equations in  $E$  are not satisfied. This implies that there is a permutation  $\pi$  such that the only edges that are mapped to non-edges and vice-versa are from at most  $t$  pairs of color classes. The same argument as in the proof of Lemma 12 shows that for any permutation  $\pi$  there is a permutation  $\sigma$  such that  $\overline{m\bar{p}}(\sigma) \leq \overline{m\bar{p}}(\pi)$  and  $\sigma$  has the following property: For any color class  $j$ ,  $\sigma$  maps all the vertices in  $V_j^0$  to  $V_j^1$  and vice-versa or is the identity mapping on that color class.

Finally we show that Min-EGI $_4$  is hard to approximate.

**Theorem 18.** *For any constant  $\alpha > 1$ , there is no  $\alpha$ -approximation algorithm for Min-EGI $_4$  unless  $\text{P} = \text{NP}$ .*

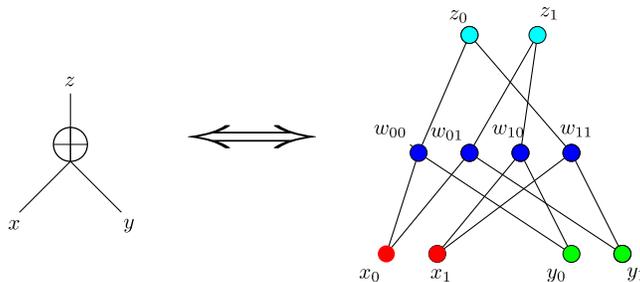

An instance of NCP consists of a subspace  $\mathcal{S}$  of  $\mathbb{F}_2^n$  given as a set of basis vectors  $\mathcal{B} = \{s_1, \dots, s_k\}$  and a vector  $v \in \mathbb{F}_2^n$ . The objective is to find a vector  $u \in \mathcal{S}$  which minimizes the hamming weight  $\text{wt}(u + v)$ , i.e., the number of bits where  $u$  and  $v$  differ. It is NP-hard to approximate NCP within any constant factor [1]. The following lemma gives a reduction that transfers this hardness to Min-EGI $_4$ .

**Lemma 19.** *There is a polynomial time algorithm that for a given NCP instance  $\mathcal{I}$ , constructs a Min-EGI $_4$  instance  $\mathcal{I}'$  with  $\text{OPT}(\mathcal{I}') = \text{OPT}(\mathcal{I})$ .*

The idea of the proof is to construct two graphs  $G_1$  and  $G_2$  such that any vector from the given subspace  $\mathcal{S}$  that is equal to  $v$  in all but  $k$  positions, can be converted into a color-preserving bijection from  $V(G_1)$  to  $V(G_2)$  that maps all but  $k$  edges to edges, and vice versa.

Let the instance  $\mathcal{I}$  be given by the vector  $v \in \mathbb{F}_2^n$  and the basis  $\mathcal{B} = \{s_1, \dots, s_m\}$  of the subspace  $\mathcal{S}$ , i.e.,  $\mathcal{S} = \{\sum_{i=1}^m \alpha_i s_i \mid \alpha_i \in \{0, 1\}\}$ . The computation of a vector  $u \in \mathcal{S}$  can be thought of as  $n$  circuits  $\mathcal{C}_1, \dots, \mathcal{C}_n$ . Thus  $\mathcal{C}_i$  computes the  $i^{\text{th}}$  bit of  $u$ , i.e.,  $\mathcal{C}_i(\alpha) = \bigoplus_{j \in [m], s_{j,i}=1} \alpha_j$ , where  $\alpha = \alpha_1 \cdots \alpha_m$  is the input and  $s_{j,i}$  is the  $i^{\text{th}}$  bit of  $s_j$ . We assume that these circuits contain only parity gates with fanin 2.

We now proceed to construct a graph  $G$  from these circuits such that there is a one-one correspondence between all assignments of values to  $\alpha$  and all automorphisms of  $G$ . For each input bit  $\alpha_j$ , add two vertices  $\alpha_{j,0}, \alpha_{j,1}$  of the same color. Assigning  $\alpha_j = 0$  corresponds to the identity permutation on this color class, assigning  $\alpha_j = 1$  corresponds to exchanging these vertices. We also add two vertices of the same color for the output of each parity gate. To get the desired correspondence between assignments and automorphisms, we use the graph gadget of Torán [22]: For a parity gate with inputs  $x$  and  $y$  which computes  $z = x \oplus y$ , the gadget  $G_{\oplus}$  connects the vertices  $x_0, x_1$  corresponding to  $x$ ,  $y_0, y_1$  corresponding to  $y$ , and  $z_0, z_1$  corresponding to  $z$  using four additional intermediate vertices  $w_{0,0}, w_{0,1}, w_{1,0}, w_{1,1}$  that receive the same (new) color. For  $b \in \{0, 1\}$ , the vertex  $x_b$  is connected to  $w_{b,0}$  and  $w_{b,1}$ , while  $y_b$  is connected to  $w_{0,b}$  and  $w_{1,b}$ . The vertex  $w_{b_1, b_2}$  is connected to  $z_{b_1 \oplus b_2}$  for  $b_1, b_2 \in \{0, 1\}$ . The construction is depicted in Figure 2.

**Fig. 2.** Gadget  $G_{\oplus}$  corresponding to a parity gate  $z = x \oplus y$  [22]

The gadget is useful due to the following lemma.

**Lemma 20 ([22]).** *There is a unique automorphism  $\phi$  for  $G_{\oplus}$  which maps  $x_i$  to  $x_{a \oplus i}$  and  $y_i$  to  $y_{b \oplus i}$  for  $a, b, i \in \{0, 1\}$ . This automorphism  $\phi$  maps  $z_i$  to  $z_{a \oplus b \oplus i}$ .*

Lemma 20 implies that the automorphisms of  $G$  exactly correspond to the valid computations of the circuits  $\mathcal{C}_1, \dots, \mathcal{C}_n$  on all possible  $2^m$  assignments. We obtain the two graphs  $G_1$  and  $G_2$  for the Min-EGI<sub>4</sub> instance  $\mathcal{I}'$  from the graph  $G$  by adding marker gadgets to the vertices corresponding to the output bits. Let  $u_{i,0}$  and  $u_{i,1}$  be the vertices corresponding to the output bit of  $\mathcal{C}_i$ . For each circuit, we add a new vertex  $u'_i$  (with a new color) in  $G_1$  as well as in  $G_2$ . In  $G_1$ , we

connect  $u'_i$  to  $u_{i,0}$  if  $v_i = 0$ , and to  $u_{i,1}$  otherwise, whereas in  $G_2$ , we connect  $u'_i$  to  $u_{i,0}$  unconditionally. Now we are ready to prove Lemma 19.

*Proof of Lemma 19.* Given an instance of NCP specified by a subspace  $\mathcal{S}$  generated by the basis vectors  $\mathcal{B} = \{s_1, \dots, s_m\}$  and a vector  $v \in \mathbb{F}_2^n$ , we construct graphs  $G_1$  and  $G_2$  as described above.

Suppose there exists a vector  $u = \sum_{i=1}^m \alpha_i s_i$  such that  $\text{wt}(u + v) \leq t$ . Given this  $\alpha$ , we construct an automorphism  $\pi_\alpha$  of  $G$  as follows: For each input node of  $\mathcal{C}_i$ , apply the automorphism on the vertices corresponding to the value of  $\alpha_i$  to it. For each parity gate, Lemma 20 specifies how to extend an automorphism to the output vertices of the gadget, given a permutation of the input vertices. Continuing this process for the whole graph we get an automorphism of  $G$  that maps the vertex  $u_{i,0}$  to  $u_{i,u_i}$ . We extend this automorphism to a mapping from  $G_1$  to  $G_2$ , fixing the output marker vertices  $u'_i$ . The only unmatched edges are those incident to the vertices  $u'_i$  with  $u_i \neq v_i$ , so all but at most  $t$  edges of  $G_1$  are mapped to edges of  $G_2$ .

Now suppose that there is a permutation  $\pi$  such that  $\overline{\text{m}e}(\pi) \leq t$  between the graphs  $G_1$  and  $G_2$ . By construction, each parity gate is used for only one output bit, so at most  $t$  output bits are affected by the mismatched edges. Thus we can convert this permutation  $\pi$  to a new permutation  $\sigma$  such that  $\overline{\text{m}e}(\sigma) \leq \overline{\text{m}e}(\pi)$  where the only edge that is mapped to a non-edge is  $(u_{i,b}, u'_i)$ . This is because for each circuit  $\mathcal{C}_j$ , starting from a permutation of its inputs, we can consistently extend the permutation till the output gate of  $\mathcal{C}_j$ . Thus depending on whether the input vertices were flipped by the permutation or not, we can assign a value to each  $\alpha_j$  and hence get a vector  $u \in \mathcal{S}$  such that  $\text{wt}(u + v) \leq t$ . This completes the proof of the lemma and finishes the proof of Theorem 18.  $\square$

## 4 Conclusion

Although GI expressed as an optimization problem was mentioned in [2], as far as we know this is the first time that the complexity of the other three variants of this optimization problem has been studied. Considering the upper and lower complexity bounds that we have proved in this paper, the following questions seem particularly interesting.

In Theorem 1 we describe an  $\alpha$ -approximation algorithm for Max-PGI that runs in quasi-polynomial time. Does Max-PGI also have a polynomial time approximation scheme? Theorem 2 shows that it is unlikely that Max-EGI has an  $(\frac{1}{2} + \varepsilon)$ -approximation algorithm. Does Max-EGI have a constant factor approximation algorithm? We can use the Quadratic Assignment Problem to get an additive error algorithm for it which runs in quasi-polynomial time but we do not know whether this algorithm can be used to get a constant factor approximation algorithm for Max-EGI (as was possible for Max-PGI). In the case of vertex-colored graphs, even though we can rule out the existence of a PTAS for Max-PGI $_k$  and Max-EGI $_k$ , it remains open whether these problems have efficient approximation algorithms providing a good constant factor approximation guarantee.

**Acknowledgement.** We thank the anonymous referees for their suggestions to improve the article.

## 5 Addons

- In the reduction from Max-2Lin-2 to Max-PGI<sub>k</sub>, we wrote that  $mp_{i,j} = 4[(k - f_j)f_i + (k - f_i)f_j]$ . This is true only when the graphs corresponding to classes  $i$  and  $j$  are from the equation  $x_i + x_j = 1$ . When the graphs come from the equation  $x_i + x_j = 0$ , then the value  $mp_{i,j} = 4[f_i f_j + (k - f_i)(k - f_j)]$ .
- Check the reduction from Min-Uncut to Min-EGI<sub>k</sub>. It is exactly like the reduction from Max-2Lin-2 to Max-PGI<sub>k</sub> and it will show that for any  $k$ , Min-EGI<sub>k</sub> has no  $\alpha$ -approximation algorithm for constant  $\alpha$  assuming the UGC.
