Rhythmic behavior is central to the normal functioning of many biological processes [1] and the periods of such oscillators span a wide range of time scales controlling almost every aspect of life [2–5]. Synchronization of spatially distributed oscillators is of crucial importance for many biological systems [6]. For example, disruption of coherent collective activity in the heart can result in life-threatening arrhythmia [7]. In several cases, the rhythmic behavior of the entire system is centrally organized by a specialized group of oscillators (often referred to as pacemakers) [8] as in the heart, where this function is performed in the sinoatrial node [9]. However, no such special coordinating agency has been identified for many biological processes. A promising mechanism for the self-organized emergence of coherence is through coupling among neighboring elements. Indeed, local interactions can lead to order without an organizing center in a broad class of complex systems [10].

The present work is inspired by studies of the pregnant uterus whose principal function is critically dependent on coherent rhythmic contractions that, unlike the heart, do not appear to be centrally coordinated from a localized group of pacemaker cells [11]. In fact, the uterus remains quiescent almost throughout pregnancy until at the very late stage when large sustained periodic activity is observed immediately preceding the expulsion of the fetus [12]. In the U.S., in more than 10% of all pregnancies, rhythmic contractions are initiated significantly earlier, causing preterm births [13], which are responsible for more than a third of all infant deaths [14]. The causes of premature rhythmic activity are not well understood and at present there is no effective treatment for preterm labor [12].

In this Letter we have investigated the emergence of coherence using a modeling approach that stresses the role of coupling in a system of heterogeneous entities. Importantly, recent studies have not revealed the presence of pacemaker cells in the uterus [15]. The uterine tissue has a heterogeneous composition, comprising electrically excitable smooth muscle cells (uterine myocytes), as well as electrically passive cells (fibroblasts and interstitial Cajal-like cells) [16,17]. Cells are coupled in tissue by gap junctions that serve as electrical conductors. In the uterine tissue, the gap-junctional couplings have been seen to markedly increase during late pregnancy and labor, both in terms of the number of such junctions and their conductances (by an order of magnitude [18]), which is the most striking of all electrophysiological changes the cells undergo during this period. The observation that isolated uterine cells do not spontaneously oscillate [15], whereas the organ rhythmically contracts when the number of gap junctions increases, strongly suggests a prominent role of the coupling. The above observations have motivated our model for the onset of spontaneous oscillatory activity and its synchronization through increased coupling in a mixed population of excitable and passive elements. While it has been shown earlier that an excitable cell connected to passive cells can oscillate [19], we demonstrate that coupling such oscillators with different frequencies (because of varying numbers of passive cells) can result in the system having a frequency higher than its constituent elements. We have also performed a systematic characterization for the first time of the dynamical transitions occurring in the heterogeneous medium comprising active and passive cells as the coupling is increased, revealing a rich variety of synchronized activity in the absence of any pacemaker. Finally, we show that the system has multiple coexisting attractors characterized by distinct mean oscillation periods, with the nature of variation of the frequency with coupling depending on the choice of initial state as the coupling strength is varied. Our results provide a physical understanding of the transition from transient excitations to sustained rhythmic activity through physiological changes such as increased gap junction expression [20].

The dynamics of excitable myocytes can be described by a model having the form $C_m \dot{V_e} = -I_{ion}(V_e, g_i)$, where $V_e$
the system is in the excitable regime and small variations of the medium (the parameter values are chosen such that
excitations away from the excitation threshold, \(A(=3)\) specifies the fast activation kinetics, and \(\epsilon(=0.08)\) characterizes the recovery rate of the medium (the parameter values are chosen such that the system is in the excitable regime and small variations do not affect the results qualitatively). The state of the electrically passive cell is described by the time evolution of the single variable \(V_p\) [22]: \(\dot{V}_p = F_p(V_p) = K(V_p - V_p^R)\), where the resting state for the cell \(V_p^R\) is set to 1.5 and \(K(=0.25)\) characterizes the time scale over which perturbations away from \(V_p^R\) decay back to it. We model the interaction between a myocyte and one or more passive cells by

\[
\begin{align*}
\dot{V}_e &= F_e(V_e, g) + n_p C_r(V_p - V_e), \\
\dot{V}_p &= F_p(V_p) - C_r(V_p - V_e),
\end{align*}
\]

where \(n_p(=1,2,\ldots)\) passive elements are coupled to an excitable element via the activation variable \(V_{e,p}\) with strength \(C_r\). Here, we have assumed for simplicity that all passive cells are identical, having the same parameters \(V_p^R\) and \(K\) as well as starting from the same initial state. We observe that the coupled system comprising a realistic model of uterine myocyte and one or more passive cells exhibits oscillations [Fig. 1(a)] qualitatively similar to the generic FHN model [Fig. 1(b)], although the individual elements are incapable of spontaneous periodic activity in both cases. In Figs. 1(a) and 1(b), the range of \(n_p\) and excitable-passive cell couplings for which limit cycle oscillations of the coupled system are observed is indicated with a pseudocolor representation of the period (\(\tau\)). We also look at how a system obtained by diffusively coupling two such “oscillators” with distinct frequencies (by virtue of having different \(n_p\)) behaves upon increasing the coupling constant \(D\) between \(V_e\) [Fig. 1(c)]. A surprising result here is that the combined system may oscillate faster than the individual oscillators comprising it.

To investigate the onset of spatial organization of periodic activity in the system we have considered a two-dimensional medium of locally coupled excitable cells, where each excitable cell is connected to \(n_p\) passive cells [Fig. 1(d)], \(n_p\) having a Poisson distribution with mean \(f\). Thus, \(f\) is a measure of the density of passive cells relative to the myocytes. Our results reported here are for \(f = 0.7\); we have verified for various values of \(f \geq 0.5\) that qualitatively similar behavior is seen. The dynamics of the resulting medium is described by

\[
\frac{dV_e}{dt} = F_e(V_e, g) + n_p C_r(V_p - V_e) + D \nabla^2 V_e,
\]

where \(D\) represents the strength of coupling between excitable elements (passive cells are not coupled to each other). Note that, in the limit of large \(D\), the behavior of the spatially extended medium can be reduced by a mean-field approximation to a single excitable element coupled to \(f\) passive cells. As \(f\) can be noninteger, \(n_p\) in the mean-field limit can take fractional values [as in Figs. 1(a) and 1(b)].

We discretize the system on a square spatial grid of size \(L \times L\) with the lattice spacing set to 1. For most results reported here \(L = 64\), although we have used \(L\) up to 1024

![FIG. 1 (color online). Oscillations through interaction between excitable and passive elements. A single excitable element described by (a) a detailed ionic model of a uterine myocyte and (b) a generic FHN model coupled to \(n_p\) passive elements exhibits oscillatory activity (inset) with period \(\tau\) for a specific range of gap-junctional conductances \(G_m\) in (a) and coupling strengths \(C_r\) in (b). The triangles (upright and inverted) enclosing the region of periodic activity in (b) are obtained analytically by linear stability analysis of the fixed point solution of Eq. (1a). (c) Frequency of oscillation for a system of two oscillators A and B (each comprising an excitable cell and \(n_p\) passive cells with \(n_p^A = 1\) and \(n_p^B = 2\)) coupled with strength \(D\). Curves corresponding to different values of \(C_r\) show that the system synchronizes on increasing \(D\), having a frequency that can be higher than either of the component oscillators. to verify that the qualitative nature of the transition to
global synchronization with increasing coupling is inde-
pendent of system size. The dynamical equations are
solved using a fourth-order Runge-Kutta scheme with
time step $dt \leq 0.1$ and a standard 5-point stencil for the
spatial coupling between the excitable elements. We have
used periodic boundary conditions in the results reported
here and verified that no-flux boundary conditions do not
produce qualitatively different phenomena. Frequencies
of individual elements are calculated using fast-Fourier trans-
form of time series for a duration $2^{15}$ time units. The
behavior of the model for a specific set of values of $f$,
$C_r$, and $D$ is analyzed over many ($\sim 100$) realizations of
the $n_x$ distribution with random initial conditions.

Figure 2 (first row) shows spatial activity in the system at
different values of $D$ after long durations ($\sim 2^{15}$ time units)
starting from random initial conditions. As the coupling $D$
between the excitable elements is increased, we observe a
transition from highly localized, asynchronous excitations
to spatially organized coherent activity that manifests as
propagating waves. Similar traveling waves of excitation
have indeed been experimentally observed in vitro in my-
ometrial tissue from the pregnant uterus [23]. The different
dynamical regimes observed during the transition are ac-
companied by an increase in spatial correlation length
scale (Fig. 2, middle row) and can be characterized by

![Figure 2](color online). Emergence of synchronization with in-
creased coupling. Snapshots (first row) of the activity $V_1$ in a
two-dimensional simulation domain ($f = 0.7$, $C_r = 1$, $L = 64$)
for increasing values of coupling $D$ (with a given distribution of
$n_x$). The corresponding time-averaged spatial correlation func-
tions $C(r)$ are shown in the middle row. The size of the region
around $r = 0$ (at center) where $C(r)$ is high provides a measure of
the correlation length scale which is seen to increase with $D$.
The last row shows pseudocolor plots indicating the frequencies
of individual oscillators in the medium (white corresponding to
absence of oscillation). Increasing $D$ results in decreasing the
number of clusters with distinct oscillation frequencies, even-
tually leading to global synchronization characterized by spa-
tially coherent, wavelike excitation patterns where all elements
in the domain oscillate with same frequency.

![Figure 3](color online). (a) Different dynamical regimes of the
uterine tissue model (for $f = 0.7$) in $D - C_r$ parameter plane
indicating the regions having (i) complete absence of oscillation
(NO), (ii) cluster synchronization (CS), (iii) local synchronization
(LS), (iv) global synchronization (GS), and (v) coherence
(COH). (b),(c) Variation of (b) width of frequency distribution
$c_{D}$ and (c) fraction of oscillating cells $f_{osc}$ with coupling
strength $D$ for $C_r = 1$ [i.e., along the broken line shown in (a)].
The regimes in (a) are distinguished by thresholds applied on
order parameters $(\sigma_r)$, $f_{osc}$, and $(F)$, viz., NO, $f_{osc} < 10^{-3}$;
CS, $(\sigma_r) > 10^{-4}$; LS, $(\sigma_r) < 10^{-4}$ and $f_{osc} < 0.99$; GS,
$(f_{osc}) > 0.99$; and COH, $(F) > 0.995$. Results shown are
averaged over many realizations.
two order parameters \( \langle \sigma_v \rangle \) and \( \langle f_{\text{osc}} \rangle \) with the coupling \( D \), \( \langle \cdot \rangle \) indicating ensemble average over many realizations. Varying the excitatory cell-passive cell coupling \( C_r \) together with \( D \) allows us to explore the rich variety of spatiotemporal behavior that the system is capable of [Fig. 3(a)]. In addition to the different synchronized states (CS, LS, and GS), we also observe a region where there is no oscillation (NO) characterized by \( f_{\text{osc}} \to 0 \), and a state where all elements oscillate with the same frequency and phase which we term coherence (COH). COH is identified by the condition that the order parameter \( F \equiv \max_t f_{\text{osc}}(t) \to 1 \), where \( f_{\text{osc}}(t) \) is the fraction of elements that are active \( (V_e > \alpha) \) at time \( t \). In practice, the different states are characterized by thresholds whose specific values do not affect the qualitative nature of the results.

To further characterize the state of the system, we determined the mean frequency \( \tilde{\nu} \) by averaging over all oscillating cells for any given realization of the system. Figure 4(a) reveals that several values of the mean frequency are possible at a given coupling strength. When the initial conditions are chosen randomly for each value of the coupling [broken curve in Fig. 4(a)], the mean frequency decreases with increasing \( D \). On the other hand, \( \tilde{\nu} \) is observed to increase with \( D \) when the system is allowed to evolve starting from a random initial state at low \( D \), and then adiabatically increasing the value of \( D \). The abrupt jumps correspond to drastic changes in the size of the basin of an attractor at certain values of the coupling strength, which can be investigated in detail in future studies. This suggests a multistable attractor landscape of the system dynamics, with the basins of the multiple attractors shown in Fig. 4(d) [each corresponding to a characteristic spatiotemporal pattern of activity shown in Fig. 4(e)] having differing sizes. They represent one or more plane waves propagating in the medium and are quite distinct from the disordered patterns of spreading activity [Figs. 4(b) and 4(c)] seen when random initial conditions are used at each value of \( D \). We note that the period of recurrent activity in the uterus decreases with time as it comes closer to term [20] in conjunction with the increase in number of gap junctions. This is consistent with our result in Fig. 4(a) when considering a gradual increase of the coupling \( D \).

Our results explain several important features known about the emergence of contractions in uterine tissue. Previous experimental results have demonstrated that the coupling between cells in the myometrium increases with progress of pregnancy [18]. This suggests that the changes in the system with time amounts to simultaneous increase of \( D \) and \( C_r \), eventually leading to synchronization as shown in Fig. 3(a). Such a scenario is supported by experimental evidence that disruption of gap-junctional communication is associated with acute inhibition of spontaneous uterine contractions [24]. The mechanism of synchronization discussed here is based on a very generic model, suggesting that our results apply to a broad class of systems comprising coupled excitable and passive cells [25,26]. A possible extension will be to investigate the effect of long-range connections [27].

To conclude, we have shown that coherent periodic activity can emerge in a system of heterogeneous cells in a self-organized manner and does not require the presence of a centralized coordinating group of pacemaker cells. A rich variety of collective behavior is observed in the system under different conditions; in particular, for intermediate cellular coupling, groups of cells spontaneously form clusters that oscillate at different frequencies. With increased coupling, clusters merge and eventually give rise to a globally synchronized state marked by the genesis of propagating waves of excitation in the medium. Our model predicts that a similar set of changes occur in the uterus during late stages of pregnancy.
